

Freely propagating flame velocity of CH₄-air vs. pressure

Background

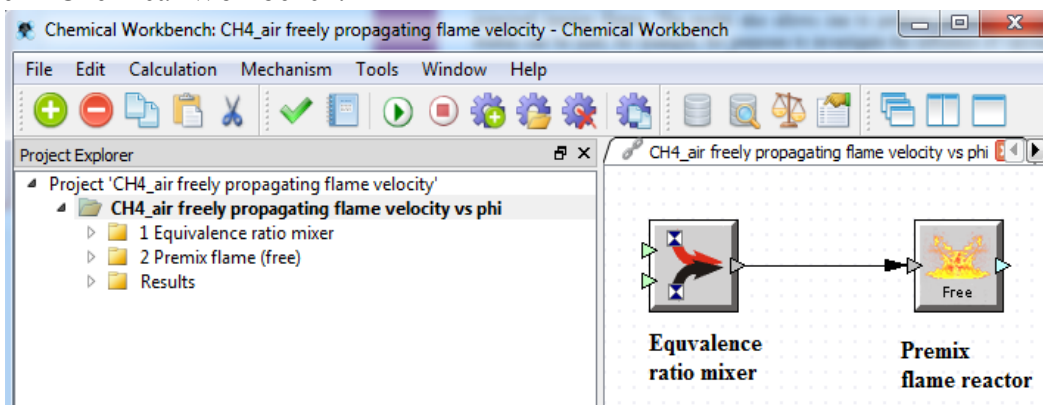

The laminar combustion properties are of fundamental importance for analyzing and predicting the performance of many combustion systems and practical combustors, such as internal combustion engines and gas turbines. The freely propagating laminar flame model is developed to model the behavior of the steady, adiabatic, freely propagating one-dimensional premixed laminar flames. The model also allows one to perform parameter studies. Parameter studies can be used, for example, to assess how the ambient conditions affect the laminar flame speed. This is a typical task encountered in internal combustion engines design, where the pressure is varying during the combustion of the fuel-air mixture

Problem statement

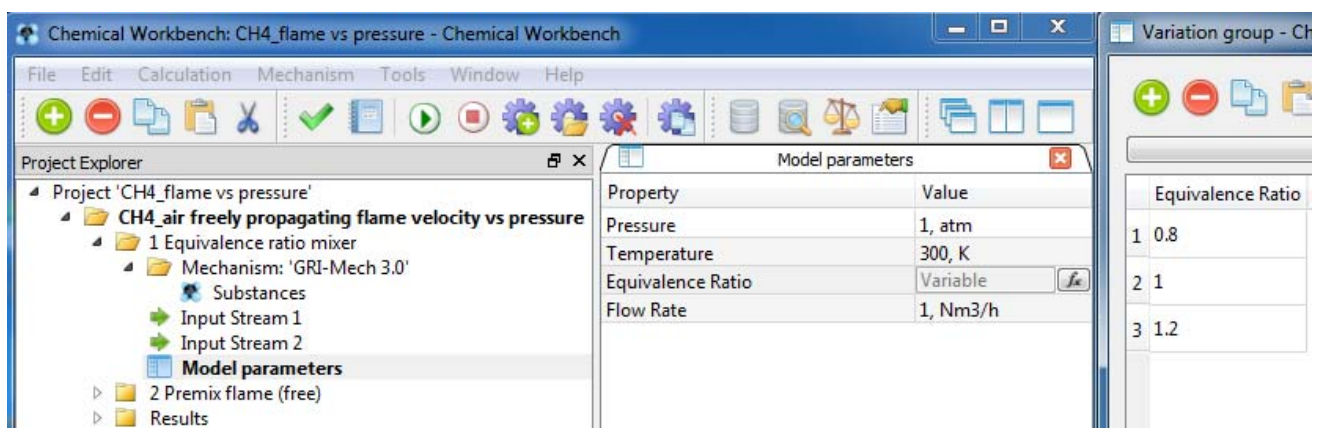

It is required to calculate the freely propagating flame velocities as function of pressure at fixed equivalence ratio for the premixed methane-air laminar flames. Initial temperature of methane-air is 300K, pressure 1- 20 atm. Mixture equivalence ratio - 0.8, 1, 1.2.

Problem setup in Chemical Workbench

This example includes the calculation of free propagation flame velocities of at $\phi = 0.8, 1, 1.2$ at $T_0 = 300$ K, $P = 1-20$ atm. To calculate flame velocities as well as temperature and main concentrations behavior during the combustion of methane-air mixture at different equivalence ratios ϕ , we use the chain of two reactors – **Equivalence Ratio Mixer** and **Premixed Flame Reactor**, available in Chemical Workbench.

The first reactor **Equivalence Ratio Mixer** calculates composition of initial mixture at given ϕ . The mixture of CH₄-air is inputted in this reactor - **Input Stream 1** - Fuel (CH₄), **Input Stream 2** – oxidizer (air). This model requires kinetic mechanism. In this case the mechanism GRIMEch-3.0 is taken. The Mechanism is loaded from KintechDB database, which is tightly integrated with Chemical Workbench.

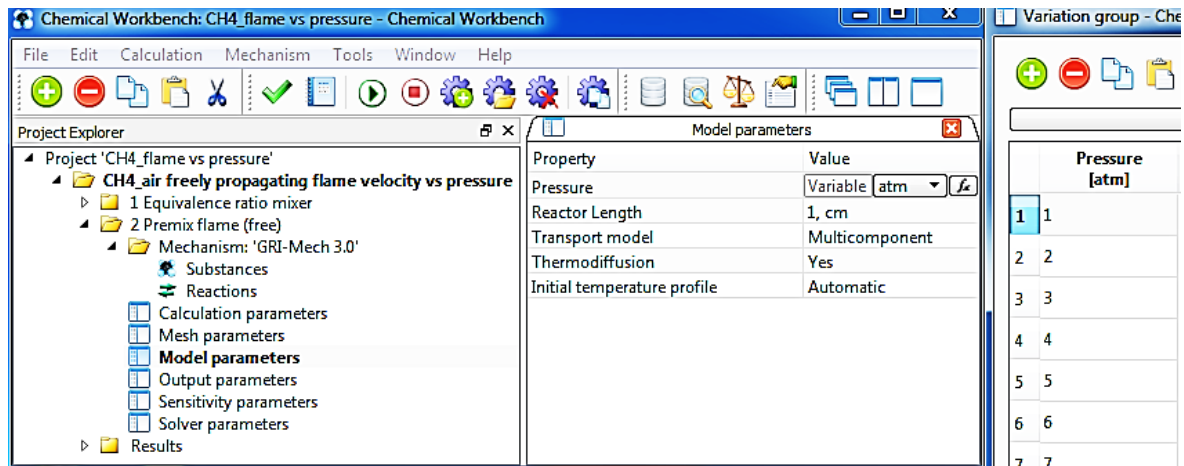

Property	Value
Pressure	1, atm
Temperature	300, K
Equivalence Ratio	Variable
Flow Rate	1, Nm ³ /h

Variation group - CH	
	Equivalence Ratio
1	0.8
2	1
3	1.2

Premixed Flame Reactor demands setting the next:

- Mechanism,
- Model parameters,
- Calculation parameters
- Solver parameters

The minimum number of input parameters, related with numerical method implementation, is required. Particularly, no initial guess on temperature profile and intermediate species concentrations is required. This simplifies setup of laminar flame simulation

The screenshot shows the 'Model parameters' window in Chemical Workbench. The parameters are as follows:

Property	Value
Pressure	Variable [atm]
Reactor Length	1, cm
Transport model	Multicomponent
Thermodiffusion	Yes
Initial temperature profile	Automatic

The Project Explorer on the left shows the simulation setup for 'CH4_air freely propagating flame velocity vs pressure', including '1 Equivalence ratio mixer', '2 Premix flame (free)', and 'Mechanism: 'GRI-Mech 3.0''. Other categories like 'Substances', 'Reactions', 'Calculation parameters', 'Mesh parameters', 'Model parameters', 'Output parameters', 'Sensitivity parameters', and 'Solver parameters' are also visible.

Results

Simulated results are shown at picture below. Experimental results are taken from [1], [2].

Laminar burning velocities of $\text{CH}_4 + \text{air}$ flames as a function of pressure for fixed equivalence ratios 0.8, 1, 1.2 at temperature 300 K.

Next steps

This example can be extended further

- 1.Run sensitivity analysis to identify reaction paths, which affect laminar burning velocity most of all
- 2.Compare predictions of different chemical kinetic mechanisms, available in KintechDB database, for conditions of interest for you
